Abstract. A Geophysical method named Ground Penetrating Radar (GPR) can be applied to geotechnical investigation to determine the underground conditions. In this study a GPR is used to detect the ballast condition of the railway track. The Ballast bed plays an important role in rail track keeping the gauge between sleepers and there by position of the rails. As the train moves over the track, ballast helps to hold the track in place. Ballast fouling is formed by coal dust and the breakdown of ballast or from soil interference under the rail track. The rail track can be damaged substantially due to the fouling material such as coal, metal piece, large stone etc. This paper presents the non-destructive testing method namely ground penetrating radar (GPR) for identification of different types of materials. To detect the underground substructures 800MHz ground coupled antenna was used. Constructed a model rail track with different fouling material are buried under the subsurface structures. This work is carried out in Civil Engineering laboratory, IISc, Bangalore.

This research work presents the detection of underground structures like different metals, big sized ballast, clean ballast etc. Find maximum change point algorithm is proposed to detect the abrupt changes in the signal, by this it will also detect the size of a target by calculating the start and end trace of the buried object. It is important for the diagnosis of ground substructures. This paper also describes the application of wavelet decomposition to detect the condition of the ballast viz clean or fouled. The wavelet decomposition finds the shape of the object by calculating the Higher order statistical parameters like skewness test and Kurtosis test.

Keywords: Ground Penetrating Radar, Change point detection, Wavelets, Skewness, Kurtosis.

1   Introduction

Ground Penetrating Radar is a nondestructive geotechnical tool for detecting the subsurface targets. It consists of transmitting antenna, receiving antenna and Display unit. The transmitting antenna transmits an electromagnetic pulse into the ground to detect and classify the various subsurface objects like metal, pipe, air cavity etc., andthe reflected pulses are picked up by the receiving antenna. The reflections from the target depends on the different dielectric value of the object. According to the general principle, if the antenna frequency increases then depth of penetration decreases with increase in resolution. The depth of penetration increases with decrease in the antenna frequency and resolution also decreases. To obtain a distinct signature of different buried objects can be detected by using image and signal processing techniques. GPR is widely used in various applications in landmine investigation, geotechnical, underground utilities, archaeology etc. The interpretation of raw GPR radargram is a challenging task as it needs a better algorithm for improved visualization of the targets.

In this work two contributions are carried out to map the subsurface targets. The wavelet transform with Higher order statistics method is implemented to map the subsurface targets. The change point method is also used to detect the abrupt changes in the signal. By change point algorithm it is easy to detect the size of the object.

2   Methodology

Processing of raw GPR images to map the subsurface targets are one of the difficult tasks. The subsurface targets are obscured with signal noise, echo, reflections from soil etc. Hence the interpretation of GPR image is one of the difficult techniques to differentiate between the target and the false target. An algorithm is implemented to detect the different signatures of the target from GPR images. The processing steps are firstly preprocessing of the GPR data, secondly applying the wavelets to the preprocessed signal and next is the detection of abrupt changes in the signal using a maximum change point method. The block diagram of the processing steps is as shown in Fig. 1.
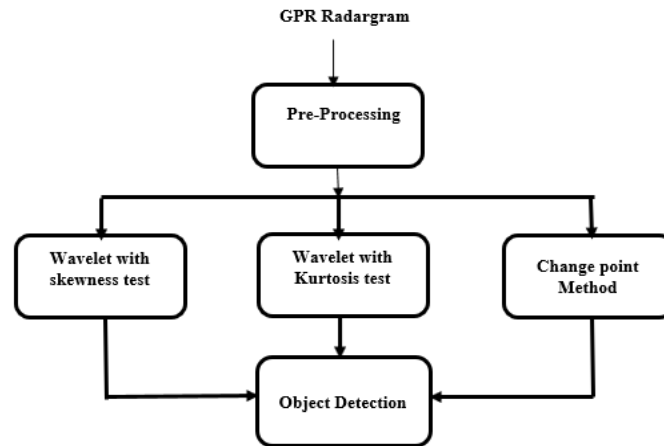

Fig.1. GPR Processing Step

3 GPR Data Collection

The Data sets are acquired from Mala GPR Machine at IISc Bangalore. The ground coupled antenna with 800MHZ has been used to acquire the information of the subsurface targets. In this work a model railway track is built at IISc without the rails and sleepers. The underground objects used are Metal (iron rod), M S steel and clean ballast. The length and width of the track is 4.8 m, 1.6 m. Ballast is used to construct a railway track. Ballast is irregular shaped stones and the height of the ballast is 0.6 m. For all these targets the reflections are different due to the dielectric value of the material.

4 Post Processing Using Wavelets and Change Point Method

4.1 Wavelet transform

The algorithm used to filter out the noise in GPR data is Discrete wavelet Transform, after that a change point method is applied to detect the abrupt changes in the signal. The wavelet transform is a multiresolution technique to extract the information content in the signal. It is used to denoise the incoming signal. By choosing the wavelet coefficients at a particular value we can convert the data into the wavelet domain. The coefficients chosen are from HoS (Higher order statistics) method. In this method we considered two tests, skewness test and Kurtosis test. A signal is decomposed into 10 levels. The wavelet coefficients of a 2d wavelet transform is given by

$$W\, P^m_{x,s}(i) = W\, P^n_{x,s}(i) + W\, P^o_{x,s}(i) \qquad (1)$$

Where W $P_{x,s}^{m}$ (i), W $P_{x,s}^{n}$ (i) and W $P_{x,s}^{o}$ (i) are wavelet packet coefficients of m, n and number of decomposition levels x = 1,2,……x. number of scales are s = n1,2,…….
i = 1, 2………K, where K = L/2 x. Where L is the length of the input signal.

The information content in the signal can be extracted by third and fourth order moments i.e. skewness and Kurtosis test.

Skewness test. It is a distribution of asymmetry of the data. If the data are perfectly symmetrical then its skewness value is zero. The value is positive if it is skewed to the left and negative for right side. It is given by the equation

$$s_3 = \sum_{i=1}^{n} \left(\frac{z_{i-} \sigma}{S}\right)^3 \tag{2}$$

Where n = size of the sample and S is the standard deviation. The third order moment of a probability model is referred to as a skewness, so it is 3.The practical formula used for the skewness is,

$$\text{Skewness} = \frac{n}{(n-1)(n-2)} \sum_{i=1}^{n} \left(\frac{z_{i-} \sigma}{S}\right)^3 \tag{3}$$

If for large samples the skewness distribution is normal with an error of $\sqrt{\frac{6}{n}}$. Hence

$$\text{Variance (Skewness)} = \frac{6}{n} \tag{4}$$

The Chebyshev inequality for any random variable y is given by

$$\text{Prob } (|S - E(S)| \geq t) \leq \frac{Var\ (S)}{t^2} \tag{5}$$

Using inequality of equation (5) the skewness test of equation (3) can be given as, $a\sqrt{\frac{6}{n}}$.

Where a $= 1/\sqrt{1-\delta}$

$$-\frac{1}{\sqrt{1-\delta}} \leq s \geq + \frac{1}{\sqrt{1-\delta}} \tag{6}$$

We have chosen a percentage of Φ = 90%.

Kurtosis test. Kurtosis is also called as a fourth order moment, which is used to measure the peak reflections of the target. It is given by the equation

$$K_a = \sum_{i=1}^{n} \left(\frac{z_{i-} \sigma}{S}\right)^4 \tag{7}$$

If the distribution is flat and long tailed, then it has a higher kurtosis value and low kurtosis value for short tailed distribution. The Practical equation is given by

$$K_a = \frac{n(n+1)}{(n-1)(n-2)(n-3)} \sum_{i=1}^{n} \left(\frac{z_{i-} \sigma}{S}\right)^4 \tag{8}$$

For large samples the distribution is normal with a error of $\sqrt{24/n}$

Using the inequality, the kurtosis with a $=\frac{1}{\sqrt{1-\delta}}$.

The kurtosis varies between $\pm \frac{1}{\sqrt{1-\delta}}$ Var (Ka).

4.2 Change point method

It is a method used for the detection of the maximum number of abrupt changes in the GPR signal to calculate the size of a target. In this the GPR signal has been analyzed by implementing a change point method by following these steps.

1. It identifies the abrupt changes in the signal.
2. To find a signal change point first it chooses a point and divides the signal into segments.
3. Next it computes an empirical estimate for the maximum number of changes for each section.
4. Within a section at each point it calculates how much it deviates from empirical value and then adds the deviations for all the points.
5. ROI (Region of Interest) of detected target is identified.
6. By this the starting trace(position) and end trace(position) of the target is easily calculated.

Let us consider a signal Y_1, Y_2, Y_3………., Y_N, the function finds 'm' number of change points such that,

$$K = \sum_{i=1}^{m-1}\left(Yi - (Y)_1^{m-1}\right)^2 + \sum_{i=m}^{N}\left(Yi - (Y)_m^N\right)^2$$

$$= \sum_{i=1}^{m-1}\left(Yi - \frac{1}{m-1}\sum_{j=1}^{m-1} \quad Yj\right)^2 + \sum_{i=1}^{m}\left(Yi - \frac{1}{N-m+1}\sum_{j=m}^{N} \quad Yj\right)^2$$

$$= m - 1 \; var \; ([Y1 \ldots\ldots\ldots Ym\text{-}1]) + N - m + 1 \; Var \; ([Ym \ldots Y N]) \quad (9)$$

So findchangepts finds 'm' such that,

$$K(M) = \sum_{i=1}^{m-1} \Delta(Yi; X([Y1 \ldots\ldots Ym-1]) + \sum_{i=1}^{m} \Delta(Yi; X([Ym \ldots\ldots YN]) \quad (10)$$

X is the empirical estimate and Δ is the deviation from empirical value.

As the number of change points increases, residual error decreases. In this algorithm a MATLAB function called findchangepts and MaxNumChanges are used to detect the abrupt changes in the GPR signal. MaxNumChanges uses an automatic threshold to detect a value of change point.

4   Results and Discussion

In this work a GPR technique operates electromagnetic (EM) waves to provide a better resolution and non-destructive measurements of different dielectric contrasts in

geological targets. When there is a target like metal or big sized ballast, it develops a strong reflection ofelectromagnetic waves because of the sharp objects present between the soil and the surrounding rock.The proposed algorithm is verified for different targets. The GPR data consists of a total number of 135 traces with a distance interval of 0. 009712 m. The length of the metal piece buried underground is 1.2m. The Model track is constructed at IISc Bangalore as shown in Fig.2. The length and breadth of the track is 4.8 m and 1.6 m. The ballast filled at a height of 0.6m. Ballast is a collection of big sized stone which plays a very important role in maintaining a good condition of the track.

Fig.2. Model Track

The signals reflected from the target are picked up by the receiving antenna. Further it is processed using MATLAB. Fig.3 is the output after applying an average subtraction trace on the GPR raw data. The Pre-Processed image is represented as a signal as shown in Fig.4.
Fig.3. GPR Image

Fig.4. Processed GPR signal in Matlab

The comparison of wavelet with Kurtosis and skewness test values for metal (Iron rod), Clean ballast and Metal circular disc are analyzed and tabulated.

Table1. Evaluation of Results using Wavelets (Skewness and Kurtosis Test)

Wavelets	Metal Track Target	No Target (ballast)	Metal Circular disc (large)	Metal Track Target	Metal Circular disc (large)	No Target
		Skewness			Kurtosis	
Haar	1.1954	0.055802	1.32125	5.3774	3.6417	1.7909
dB2	1.2128	0.20548	1.30761	4.288	4.1728	1.6484
dB3	1.3041	0.26402	1.18864	4.7827	3.5847	1.6569
Sym2	1.2128	0.20548	1.30761	4.288	4.1728	1.6484

Table.1 shows the comparison of various targets with skewness and kurtosis tests. It is clearly understood that dB3 performs better compared to the other mother wavelets. Kurtosis test performs better w.r.t the higher values than skewness test.
Fig.5. Applied Change point method (Target- Metal 1)

In this Fig.5. The GPR signal is partitioned into two segments. In each segment the points are at a minimum distance from maximum number of changes. For metal targets it accurately detected the target by considering two change points between the trace 25 and 45. By this it is easy to calculate the size of the target which is discussed in Table.2.The targets used are Metal 1 (Iron rod),Metal 2(MS Steel – Large Circular Disc) and Metal 3(MS Steel -Small Circular Disc).

Table2. Comparison of results Using Change point method.

Object	Traces	Distance Interval	Actual Value	Obtained Value- (Change Point method)	Error in %	SN R	Resolution
Metal 1	135	0.009712	0.2m	0.19m	5%	47	1.0296
Metal 2	42	0.009712	0.12 m (Dia)	0.11m	8.3 %	38	1.0296
Metal 3	37	0.009712	0.08m (Dia)	0.072m	10.05 %	36	0.8261

By implementation of maximum change point algorithm, it is accurately identified the size of the target in all the three cases with error of 5% and resolution of approximately 1.0.

5   Conclusion

The application of GPR in the field of Geotechnical Engineering gives a better result in interpretation of radargrams by implementing a wavelet algorithm with Higher order statistics and change point method for detection of the various target. Wavelet transform is applied on raw GPR data to remove the unwanted noise. Haar, dB2, dB3, Sym2 and Sym8 mother wavelets are applied on GPR data to extract the useful information. The two tests called skewness and Kurtosis are carried out. In this kurtosis performs better compared to the skewness test. Later a change point method is implemented to identify the size of the target. A MATLAB function called findchangept is used accurately to find the total number of traces in which the object is buried underground. The change point method works better to estimate the size of the target.
